Short title: HCV prevalence in Italian regions: an update

SUMMARY

This study provides an update on hepatitis C virus (HCV) estimates across Italy up to January 2021. A mathematical probabilistic modelling approach, including a Markov chain for liver disease progression, was used to estimate current HCV viraemic burden. Prevalence was defined by geographic area using an estimated annual historical HCV incidence by age, treatment, and migration rate from the Italian National database. Viraemic infection was estimated for the main HCV transmission routes by stages F0-F3 (patients without liver cirrhosis, i.e., potentially asymptomatic) and F4 (patients with liver cirrhosis, i.e., potentially symptomatic). By January 2021, we estimated that there were 398,610 individuals in Italy with HCV (prevalence of 0.66%; 95% CI: 0.66-0.67%), of which 287,730 (0.48%; 95% CI: 0.46-0.59%) were stage F0-F3. Prevalence values for all individuals with HCV were: North 0.54% (95% CI: 0.53-0.54%), Central 0.88% (95% CI: 0.87-0.89%), South 0.72% (95% CI: 0.71-0.73%), and the Isles 0.67% (95% CI: 0.66-0.68%). The population at risk for previous/current drug injection accounted for 48.6% of all individuals with HCV. A modelling approach such as this to estimate and update the prevalence of active HCV infection could be a useful methodology for the evaluation of healthcare policies related to HCV elimination plans.

Key words: HCV, undiagnosed, hepatitis C infection, prevalence, Markov chain

INTRODUCTION

Hepatitis C Virus (HCV) infection is the global leading cause of liver-related morbidity and mortality, and recent estimates report as many as 58 million individuals had chronic HCV in 2020 (Polaris Observatory HCV Collaborators, 2017; *World Health Organization: Hepatitis C* 2021; https://www.who.int/news-room/fact-sheets/detail/hepatitis-c). A high proportion of individuals do not show symptoms of the disease for decades, although the rate of disease progression increases with age (Hajarizadeh et al., 2013; Sweeting et al., 2006).

Since direct-acting antiviral drugs (DAAs) have become available for the successful treatment of HCV infection (Afdhal et al., 2014; Sulkowski et al., 2014), attention has focussed on identifying infected individuals. Only through the identification of this population will it be possible to achieve 2030 World Health Organization elimination targets (*WHO: Global health sector strategy on viral hepatitis 2016-2021*, pp. 2016–2021; https://apps.who.int/iris/handle/10665/246177).

Historically, Italy has been considered the country with the highest rate of HCV prevalence in Western Europe (Bellentani et al., 1999; Guadagnino et al., 1997; Kondili et al., 2021a; Maio et al., 2000). However, a prevalence of around 1% (95% uncertainty interval: 0.4-1.4%) has recently been estimated using the "Polaris" model, which is grounded in the natural history of HCV progression and forecasts the HCV burden on the Italian general population (Blach et al., 2022). The reported number of patients treated annually, as tracked in the Italian Medicines Agency (*Agenzia Italiana del Farmaco*; AIFA; https://www.aifa.gov.it/aggiornamento-epatite-c) Monitoring Registry for DAAs, was allocated to the age and liver disease stage of the eligible population with HCV by the relative size of the population in each treatment disease stage (Kondili et al., 2018). A free screening program has now been implemented in Italy, with a specific fund approved by law, although decentralized HCV models are still being used without any uniform strategies across different regions (Kondili et al., 2021a, 2020a). The coronavirus disease 2019 (COVID-19) pandemic has increased existing challenges in diagnosis and linkage to care of individuals with HCV (Blach et al., 2021; Kondili et al., 2021c; Mennini et al., 2021). We have recently published national estimates on the number of individuals with HCV up to January 2020 by using a probabilistic approach to estimate the infection rate and a Markov model for liver disease progression in different Italian regions (Kondili et al., 2022a). The present analysis extends these findings further to January 2021, with the goal to update the HCV infection burden by considering the potential role of screening and diagnosis during the pandemic period.

MATERIALS AND METHODS

Study design

A previously validated mathematical model was used for this study (Kondili et al., 2021b). The model was divided into two distinct computations. It computes the number of infected individuals on a national basis from available literature and the Italian National database ("Statistiche Istat," http://dati.istat.it/Index.aspx) by age, transmission route, and fibrosis stage from 1952 to October 2021. Using the above-described methodology, the model also provides the number of individuals with HCV, subdivided by age, transmission route, and fibrosis status by geographic macroarea from 2002 to January 2021 (Kondili et al., 2022a, 2021b).

Study population and literature search

Data on HCV prevalence by route of infection in high risk groups was obtained from a literature search, as previously described elsewhere (Kondili et al., 2021b).

The model

An evolutionary HCV transmission model was developed and implemented using the open-source programming language Python 3.7. The first stage of the model has been previously reported (Kondili et al., 2021b), beginning in 1952 to the end of 2001 calculating the number of infected individuals by age, transmission route, and fibrosis stage. The evolutionary steps considered the insertion of new-borns, new infections (the model accounts for six transmission routes), possible fibrosis evolution (computed using a Markov chain approach), HCV treatment, and liver-related mortality rate. All cause-mortality was also considered (see below). After this stage, the number of individuals with HCV was subdivided for each region considering the distribution of the population and the variability of risk factors among the different regions as explained in the section "Transmission routes and associated risk." Subsequently, the evolution of the HCV transmission and liver disease progression among the Italian population was performed up to January 2021, with a specific method that included the migration of people (inter-regional and international), referred to as *regional infection burden evaluation.*

An overview of these steps is described below.

1) New-borns: The number of new-borns was added (data were derived from the Italian National database [ISTAT]) ("Statistiche Istat," http://dati.istat.it/Index.aspx).
2) Internal and external migration (i.e., the movement of people from one Italian region to another or from a foreign country to Italy, respectively). For internal migration, the number of individuals was

included independent of age, whereas for external migration a minimum breakdown by age was considered using data derived from ISTAT ("Statistiche Istat," http://dati.istat.it/Index.aspx).

3) Individuals with HCV: Individuals recently contracting HCV per region, age, and year were considered (Kondili et al., 2021b). The number of new HCV cases was then calculated following the infection probabilities, depending on age, transmission route ("SEIEVA - Sistema Epidemiologico Integrato dell'Epatite Virale Acuta," https://old.iss.it/web/guest/seieva/chi-siamo), and current year.
4) Treated patients: The estimated number of patients treated with anti-viral therapy (i.e., interferon- and DAA-based treatments) was subtracted from the population with HCV based on expert data provided by EpaC onlus Patient Association up to 2014 (https://www.epac.it/) and AIFA Registry data for DAA monitoring since 2015 ("Aggiornamento dati Registri AIFA DAAs - Epatite C cronica," https://www.aifa.gov.it/aggiornamento-epatite-c). Estimates from the Italian Platform for the Studies of Viral Hepatitis Therapies (PITER) cohort, for unclassified fibrosis stage by AIFA Registry, were also used (Kondili et al., 2021b, 2017). The average number of individuals successfully treated and subtracted were 2,000 every year from 1993 to 2000 and 7,000 every year from 2001 to 2014. The number of treated patients was based on AIFA Monitoring Registry for DAA (https://www.aifa.gov.it/aggiornamento-epatite-c) data as follows: from 2015 to 2017 (mainly prioritized treatment criteria). an average of 36,296 patients each year was subtracted at a 95% rate of sustained virologic response from the number of total infected patients. Following universal treatment since 2017, a total of 56,499 treated patients for 2018, 36,348 treated patients for 2019, and 15,664 treated patients for 2020 were subtracted each year at a 98% rate of sustained virologic response from the total of infected patients.
5) Fibrosis evolution: Individuals with HCV who were considered to undergo a possible fibrosis progression according to a Markov chain probability evolution process (Kondili et al., 2021b).
6) Mortality: The number of annual deaths per region and age provided by ISTAT ("Statistiche Istat," http://dati.istat.it/Index.aspx) was subtracted. In our model, we accounted for HCV-related mortality by considering the average values of transition probabilities following the F4 fibrosis stage reported by Linthicum et al., 2016 (Linthicum et al., 2016) and Kondili et al., 2017 (Dienstag et al., 2011; Kondili et al., 2017; Townsend et al., 2011; Wright et al., 2006). All transition probabilities were adjusted for competing probabilities of death from other causes according to official data [ISTAT]("Statistiche Istat," http://dati.istat.it/Index.aspx).

Transmission routes and associated risk

The model independently tracked each transmission route, distributing the weight of the effect of each route over time, as previously described (Kondili et al., 2021b). Data for the following high-risk routes of HCV transmission were considered: previous or current drug injection, tattoos or body piercing, sexual transmission, glass syringe, blood transfusion, and vertical transmission. Key criteria for input of data in the model regarding age and year of infection were defined for each risk group. Based on HCV prevalence and the time-series of the Italian population, we reconstructed the probability of infection for ages 0-100, for years 1952 to 2021, and for the six different infection routes.

The total burden of infection at the beginning of 2002 was obtained using the results of the national phase (Kondili et al., 2021b), divided for each macroregion. The criteria used to distribute the burden of infection across different macroregions are described below for each high-risk route of infection.

a) History of previous or current drug use

The distribution of previous or current drug use was estimated according to the 2002 national report on drug addiction (*Relazione Annuale Al Parlamento Sullo Stato Delle Tossicodipendenze in Italia 2002*, 2002; http://www.edscuola.it/archivio/handicap/tossicodipendenze02.pdf). Distribution of this risk factor was also based on the number of individuals with HCV in proportion to the number of individuals under treatment in a drug addiction service (SERD; *Servizi per le Tossicodipendenze*) according to fractions. Peak age of infection was 27 years, and HCV infection through injection of drugs was assumed to begin in 1970.

b) History of tattoo or body piercing

Nationally, ages of infection from tattoo or body piercing were between 15 and 70 years, with a peak age of 35 years (Kondili et al., 2021b). However, data were not available to evaluate the prevalence of this route of infection across different regions; therefore, the number of individuals with HCV was subdivided proportionally to avoid errors in estimates. A region yields the number of those with HCV for a given age group proportionally to the number of those of that age in the region.

c) Sexual transmission

Due to the lack of available data for the route of sexual transmission, we applied the same formula as that for the route of tattoo and body piercing (Kondili et al., 2021b). Transmission of HCV in this population occurred from 15 to 65 years of age (peak age of 35 years).

d) Previous glass syringe use

A higher prevalence was assumed to have occurred at an early age (0-8 years) due to glass syringe vaccination since 1950. However, neither infection by glass syringe (in 1975, the single use of disposable

plastic syringes became law in Italy, substituting glass syringes nationwide) nor blood transfusion routes were considered in any new HCV cases since 2002; therefore, these routes can be referred to as "extinct" for the regional phase.

e) Risk of infection by blood transfusion in the past

Since blood transfusion was more likely to occur at older ages due to surgical intervention, the peak risk was centred at around 60 years of age. The age distribution profile started when the model began and peaked in the nineties (when the virus was finally isolated), and decreased gradually in subsequent years.

f) Vertical transmission

The risk of vertical transmission was calculated from the number of mothers with HCV; these females transfer the virus to new-borns at a given percentage (values retrieved from ISTAT]). The risk was estimated to be around 5.8% (Hofstraat et al., 2017; "Statistiche Istat," http://dati.istat.it/Index.aspx). Reduction of the risk has been modelled with a linear decrease up to 0.015% (Kondili et al., 2021b).

Markov chain progression for fibrosis evolution

The evolution from one stage to the next was modelled according to a Markov chain approach, previously described elsewhere (Kondili et al., 2021b). Briefly, the following annual transition probabilities were used in the reference case: F0→F1 = 7.6%, F1→F2 = 9.5%, F2→F3 = 10.8%, and F3→F4 = 13.4% (Linthicum et al., 2016). It was assumed that not more than one transition per year could occur per patient, and potential spontaneous liver fibrosis regression was not considered.

Sensitivity analysis

Sensitivity analysis was performed using a Monte Carlo approach to estimate the effect of each input on the number of estimated individuals with HCV and their annual distribution among F0-F4 stages as described previously in detail (Kondili et al., 2022a, 2021b). In brief, we repeatedly ran the model for 1,000 simulations, each time randomly picking the value of some input parameters (still around the values), and we assessed the effect of this randomization on the results of the model. Our Monte Carlo scheme intercepts two different types of randomization: risk distribution and transition probabilities. This approach considered the uncertainty in annual distribution among the F0-F4 stages, in the fibrosis annual transition probabilities, and the probability of self-curing (recover spontaneously without treatment). In each simulation, the self-curing and transition probabilities were derived (independently) from their predefined random distributions. We also conducted a sensitivity analysis of our model by transmission route for the different macroareas for individuals with stage F0-F3 and F4 (Kondili et al., 2022a). Sensitivity analysis provides information on the margins for which prevalence estimates are valid, so as

to understand the degree of variability in the data. The output of the Monte Carlo consisted of mean values of the different prevalence values computed using our model, together with a 95% confidence interval (CI), from 2.5 to 97.5 percent for each.

RESULTS

HCV prevalence estimates by Italian macroarea

The number of individuals with HCV in Italy in January 2021 was estimated at 398,610 (prevalence of 0.66%; 95% CI: 0.66-0.67%). Higher prevalence estimates were seen in regions of Central Italy (0.88%; 95% CI: 0.87-0.89%), such as Umbria (1%) and Marche (1%), followed by the South (0.72%; 95% CI: 0.71-0.73%), such as Basilicata (0.83%) and Calabria (0.81%), and the Isles (0.67%; 95% CI: 0.66-0.68%), in regions such as Sicily (0.66%) and Sardinia (0.71%); the lowest values were seen in regions in the North (0.54%; 95% CI: 0.53-0.54%), such as Piedmont (0.67%) and Veneto (0.6%) (Table 1 and Figure 1). The distributions of HCV prevalence in potentially asymptomatic individuals (stage F0-F3, i.e., patients without liver cirrhosis; estimated to be 287,730) and those with F4 stage disease (patients with liver cirrhosis, thus potentially symptomatic; estimated to be 110,880) for the 4 macroareas are summarised in Table 1. While the prevalence values for individuals with stage F0-F3 across the four macroareas were similar, varying from 0.43% to 0.59%, and similar to the overall prevalence for this stage (0.48%; 95% CI: 0.46-0.59%) (Table 1), prevalence values for individuals with stage F4 disease were generally two-fold lower than those with stage F0-F3, apart from the North, where it was approximately four-fold less (0.11% of F4 vs. 0.43% of those with F0-F3 fibrosis stage) (Table 1).

HCV prevalence by high-risk transmission route

Marked differences in overall prevalence estimates across the six high-risk infection routes were observed (Table 2). The highest prevalence was observed by previous or current drug use (0.32%; 95% CI: 0.32-0.33%) followed by previous or current tattoo use (0.17%; 95% CI: 0.16-0.17%). Stratifying by macroarea showed little variation in prevalence estimates for each infection route (Table 3).

Sensitivity analysis

Ranges in variability of estimates by fibrosis stage and age of cohort by sensitivity analysis were obtained as final results of the computations (up to January 2021). Variations around the mean values and CI ranges were computed by 1,000 Monte Carlo simulations. Specifically, the overall percentage variations around prevalence values were 0.42%-0.83%, for variations within 95% confidence intervals. The

variations in 95% confidence intervals were 2.7-5.4% for F0-F3 and 7-14% for F4, indicating the robustness of our model's findings.

DISCUSSION

The present study confirms findings from our recent regional analysis of the prevalence of HCV across Italy up to January 2020 (Kondili et al., 2022a, 2021b) and extends them to provide more recent estimates up to January 2021. Compared with our present findings, after 12 months (up to January 2021) and by using the same modelling approach, we have observed a slight decrease of 10,389 in the overall absolute number of individuals with HCV compared with estimates for the previous year (409,183 in January 2020 vs. 398,610 in January 2021). While the number of individuals with stage F0-F3 decreased from 300,171 to 287,981 (a decrease of 4.1%), the number of those with stage F4 (symptomatic) increased slightly, from 109,012 to 110, 813 (1,800 individuals and an increase of 1.6%).

The estimated number (and distribution across Italy) of patients with F4 cirrhosis is concerning and was not expected, considering their potential symptomatic disease and the high importance of viral eradication in these patients, who have been prioritized for treatment since 2015 when DAAs became available. The lack of early diagnosis in people with severe liver damage has also been documented by the AIFA DAA monitoring registry, which reported 20% of patients treated having a diagnosis of liver cirrhosis from 2019 to date ("Aggiornamento dati Registri AIFA DAAs - Epatite C cronica," https://www.aifa.gov.it/aggiornamento-epatite-c), patients that would have been diagnosed from 2015 in Italy. In addition, many people with viral hepatitis are still diagnosed too late (Lazarus et al., 2019), often resulting in increased risk of severe liver complications and death (Picchio et al., 2021). Furthermore, several studies conducted in the opportunistic screening setting still suggest a high prevalence of individuals with active infection in severe stages of liver disease who have not yet been treated (Piazzolla et al., 2021). These data imply that intervention focusing on case finding needs to be improved to ensure earlier diagnosis of populations at risk of disease progression. In terms of disease control, it is also important to increase our understanding of medical barriers that limit access to healthcare in different settings, starting from the general practitioner's awareness and clinical behaviour to patients with high risk of HCV infection and signs of chronic severe liver damage. Our findings indicate an estimated 110,880 individuals in need of urgent diagnosis, immediate linkage to care, and treatment to eradicate HCV infection to stop liver disease progression.

Considering the different factors for high risk of infection, people 46-55 years of age who previously injected or currently inject drugs and those who had undergone aesthetic procedures such as tattoos or

body piercing were identified as the main populations in which higher prevalence of undiagnosed asymptomatic individuals (stage F0-F3 disease) is expected, with similar distribution across regions (Kondili et al., 2021b). In these populations of potentially asymptomatic individuals, active HCV screening should be implemented across Italy to identify the submerged population of asymptomatic people with chronic HCV infection, as the required step toward achieving HCV elimination. This focused screening approach, if appropriately undertaken, would identify a high rate of individuals with HCV, due to the higher rate of infection related to risk factors in the younger population (drug use and aesthetic procedures at risk), and simultaneously reduce onward viral transmission by clearing HCV from those who are also at higher risk of spreading the infection (Kondili et al., 2022b).

Although a higher estimated HCV prevalence of undiagnosed individuals was seen in some specific regions in Central Italy and in the Basilicata and Calabria regions in the South, similar but slightly lower prevalence estimates of undiagnosed individuals were generally observed across the four macroareas. This would suggest a decrease in the overall level of prevalence in HCV infection compared with the past in Italy, where higher prevalence values and a gradient from North to South (3.9% in Veneto to 16.2% in Campania) was related mainly to the nosocomial transmission of infection (A.I.S.F, ASSOCIAZIONE ITALIANA PER LO STUDIO DEL FEGATO, https://www.webaisf.org/per-il-paziente/le-malattie-del-fegato/; Guadagnino et al., 1997). Despite using a different approach compared with the modelling used to estimate the global HCV burden, the results of this modelling study report an estimation within the range reported for overall active infection in Italy up to 2020. Specifically, an overall prevalence of 1% has been estimated up to 2020, with ranges varying from 0.4-1.4%, by the Polaris Observatory (Blach et al., 2022), whereas this differential modelling of the HCV infection burden by transmission route granularity in Italy up to January 2021 shows a prevalence of active infection of 0.66% (0.66-0.67). These two independent estimates are very similar, confirming the robustness of this modelling approach, and suggest that Italy is currently not a country with high HCV endemic levels. However, in terms of achieving the elimination target, screening for active HCV infection is the only currently available tool for reaching asymptomatic individuals and ensuring their linkage to care and viral eradication. In this regard, despite these relatively low prevalence values compared with past values, the screening tools for the birth 1948-1988 cohort have been shown to be highly cost-effective in Italy (Kondili et al., 2020a).

Analyses for the present study were performed up to January 2021, therefore including data up to 1 year after the severe acute respiratory syndrome coronavirus 2 virus pandemic (WHO, https://covid19.who.int/table). It is well documented that healthcare facilities across all Italian regions

had to be re-organized in order to cope with the increased number of patients with COVID-19 admitted to emergency departments, resulting in the postponement of medical services and procedures considered "non-essential" or "deferrable." The reduction in the treatment rate seen in 2019 and the nearly complete interruption of DAA treatment during the COVID-19 pandemic are likely to impact directly on the management of HCV and are of serious concern (Blach et al., 2021). A recent nationwide survey undertaken by the Italian Association for the Study of the Liver highlighted a significant decrease and suspension in the number of outpatient visits and prescriptions of antiviral treatment, which partially recovered 1 year later. However, the increase in outpatient visits was not followed by an increase in DAA prescriptions ("Aggiornamento dati Registri AIFA DAAs - Epatite C cronica," https://www.aifa.gov.it/aggiornamento-epatite-c; Aghemo et al., 2020; Mennini et al., 2021; Ponziani et al., 2021). The potential impact of this deferral has been specifically assessed in a separate analysis, where it was estimated that deferring DAA treatment for a further 6 months could increase the number of deaths from liver-related disease in HCV patients in Italy to more than 500 patients after 5 years (Kondili et al., 2020b). Regions that have experienced a high number of cases of patients hospitalized for COVID-19, such as Lombardy, may be more susceptible to deferral in DAA treatment (Buoro et al., 2020).

Limitations

The impact of other less-frequent transmission routes was not considered in the present analysis, and this limitation may have resulted in an underestimation of the observed prevalence values. Non-liver related mortality (i.e., natural mortality due to other causes) was based on ISTAT data (Italian Mortality Registry), which does not specify the cause of death and may have led to a potential overestimation of the population living with HCV infection (i.e., F4 stage disease). Another limitation is the high number of unregistered immigrants (potentially asymptomatic and undiagnosed for HCV) (Coppola et al., 2019; Fedeli et al., 2019; Massimo et al., 2018) in Italy who were not considered in our estimations. Further studies are needed to explore the impact of the immigrant population on HCV prevalence.

CONCLUSION

Findings from the present analysis showed that the number of individuals with HCV in Italy was estimated at 398,610 in January 2021 (prevalence of 0.66%; 95% CI: 0.66-0.67%). Based on data derived from this modelling study, it is necessary to stress the importance of promoting attentive case finding and linkage to care in individuals with symptomatic liver disease (estimated to be 110,880) in addition

to the active screening of asymptomatic people (estimated to be 287,730) in order to reduce prevalence, limit incidence, and potentially achieve the elimination of HCV in Italy.

Acknowledgments

The authors wish to thank Francesca Petrarca, PhD (Analytics Group, IWS Consulting SRL, Rome, Italy), for performing statistical modelling and Colin Gerard Egan, PhD (CE Medical Writing SRLS, Pisa, Italy), for his support in medical writing, both funded by AbbVie.

Funding

The design, study conduct, and financial support for the study were provided by AbbVie. AbbVie participated in the interpretation of data, review, and approval of the publication.

Conflicts of interest

LAK received teaching grants from AbbVie and Gilead. MA received funding for membership on Advisory Boards, for the preparation of educational materials, for research and educational grants, for membership on speaker panels and for support for travel to conferences from the following companies: Gilead Sciences, Janssen-Cilag, Viiv Healthcare, Merck Sharp and Dohme, Abbvie, Angelini, Pfizer, GSK, Menarini. AA serves on the advisory boards for AbbVie, Gilead, MSD, Intercept, Sobi, and Mylan and has received speaker fees from AbbVie, Gilead, Sobi, and Alfasigma. CMM received an advisor/speaker grant from AbbVie, Gilead, MSD, ViiV, Janssen-Cilag. AC has nothing to disclose. RM and VG are AbbVie employees and may own AbbVie stocks and options.
